

**METHOD OF VARYING THE BIT RATE OF THE
DATA STREAM OF CODED VIDEO PICTURES**

Field of the Invention

The present invention relates in general to the processing of digitized pictures, and, in particular, to a technique for varying the bit-rate of a data stream of digitized video pictures.

The present invention is also applicable to processing systems of coded video pictures. Due to the particular importance of the MPEG standard in treating digitized video sequences, reference will be made to an MPEG2 system for illustrating application of the present invention. In addition to an MPEG2 system, the method of the invention may also be used in processing systems that transfer video sequences based on other type standards.

15

Background of the Invention

Video coding according to the MPEG2 standard will be discussed below. The MPEG (Moving Pictures Experts Group) standard defines a set of algorithms dedicated to the compression of sequences of digitized pictures. These techniques are based on the reduction of the spatial and temporal redundancy of the sequence. Reduction of spatial redundancy is achieved by compressing independently the single images using

09712509-24400

quantization, discrete cosine transforms (DCT) and Huffman coding.

The reduction of temporal redundancy is obtained using the correlation that exist between 5 successive pictures of a sequence. Approximately each image can be expressed locally as a translation of a preceding and/or successive image of the sequence. To this end, the MPEG standard uses three kinds of pictures, indicated with an I (Intra Coded Frame), P 10 (Predicted Frame) and B (Bidirectionally Predicted Frame). The I pictures are coded in a fully independent mode. The P pictures are coded with respect to a preceding I or P picture in the sequence. The B pictures are coded with respect to two pictures, 15 an I or P kind, with the preceding one and the following one in the video sequence (Figure 1).

A typical sequence of pictures may be as follows: I B B P B B P B B I B... This is the order in which they will be viewed. However, given that any P 20 is coded with respect to the preceding I or P, and any B is coded with respect to the preceding and following I or P, it is necessary that the decoder receive the P pictures before the B pictures, and the I pictures before the P pictures. Therefore, the order of 25 transmission of the pictures will be I P B B P B B I B B...

Pictures are processed by the coder sequentially in the indicated order, and are successively sent to a decoder which decodes and 30 reorders them, thus allowing their successive displaying. To code a B picture it is necessary for the coder to keep in a dedicated memory buffer, called a frame memory, the I and P pictures coded and thereafter decoded, to which current B picture refers. 35 This requires an appropriate memory capacity.

One of the most important concepts in coding is motion estimation. Motion estimation is based on the following consideration. A set of pixels of a frame of a picture may be placed in a position of a successive picture obtained by translating the preceding one. These transpositions of objects may expose parts that were not visible before as well as changes of their shape, e.g., during a zooming.

The family of algorithms suitable to identify 10 and associate these portions of pictures is generally referred to as motion estimation. Such an association of pixels is instrumental to calculate a difference picture, thus removing redundant temporal information and making more effective the successive processes of DCT 15 compression, quantization and entropic coding.

A typical example of a method using the standard MPEG2 will now be discussed. A block diagram of a video MPEG2 coder is depicted in Figure 2. Such a system is formed by the following functional blocks.

20 Chroma filter block from 4:2:2 to 4:2:0. In
this block there is a low pass filter operating on the
chrominance component which allows the substitution of
any pixel with the weighed sum of neighboring pixels
placed on the same column and multiplied by appropriate
25 coefficients. This allows a successive subsampling by
two, thus obtaining a halved vertical definition of the
chrominance.

Frame ordinator. This blocks is composed of one or several frame memories outputting the frames in the coding order required by the MPEG standard. For example, if the input sequence is I B B P B B P etc., the output order will be I P B B P B B ... The Intra coded picture I is a frame or a semi-frame containing temporal redundancy. The Predicted-picture P is a frame or semi-frame from which the temporal redundancy with respect to

the preceding I or P (precedingly coded/decoded) has been removed. The Biredirectionally predicted-picture B is a frame or a semi-frame whose temporal redundancy with respect to the preceding I and successive P (or preceding 5 P and successive I) has been removed. In both cases the I and P pictures must be considered as already coded/decoded.

Estimator. This is the block that removes the temporal redundancy from the P and B pictures.

10 DCT. This is the block that implements the discrete cosine transform according to the MPEG2 standard. The I picture and the error pictures P and B are divided in blocks of 8*8 pixels Y, U, and V on which the DCT transform is performed.

15 Quantizer Q. An 8*8 block resulting from the DCT transform is then divided by a quantizing matrix to reduce the magnitude of the DCT coefficients. In such a case, the information associated to the highest frequencies which are less visible to human sight tend to 20 be removed. The result is reordered and sent to the successive block.

Variable Length Coding (VLC). The codification words output from the quantizer tend to contain a large number of null coefficients followed by non-null values. 25 The null values preceding the first non-null value are counted and the count figure forms the first portion of a codification word, and the second portion of which represents the non-null coefficient.

These pairs tend to assume values more probable 30 than others. The most probable ones are coded with relatively short words composed of 2, 3 or 4 bits while the least probable are coded with longer words. Statistically, the number of output bits is less than in the case such a criterion is not implemented.

0097472509 - FILE 400

Multiplexer and buffer. Data generated by the variable length coder, i.e., the quantizing matrices, the motion vectors and other syntactic elements are assembled for constructing the final syntax considered by the MPEG2 standard. The resulting bitstream is stored in a memory buffer, the limit size of which is defined by the MPEG2 standard requirement that the buffer cannot be over filed. The quantizer block Q supports such a limit by making the division of the DCT 8*8 blocks dependent upon on how far the system is from the filling limit of such a memory buffer, and on the energy of the 8*8 source block taken upstream of the motion estimation and DCT transform steps.

Inverse Variable Length Coding (I-VLC). The 15 variable length coding functions specified above are executed in an inverse order.

Inverse Quantization (IQ). The words output by the I-VLC block are reordered in the 8*8 block structure, which is multiplied by the same quantizing matrix that was used for its preceding coding.

Inverse DCT (I-DCT). The DCT transform function is inverted and applied to the 8*8 block output by the inverse quantization process. This permits passing from the domain of spatial frequencies 25 to the pixel domain.

Motion Compensation and Storage. At the output of the I-DCT, one of the following two items may exist. A decoded I frame (or semiframe) that must be stored in a respective memory buffer for removing the 30 temporal redundancy with respect thereto from successive P and B pictures. A decoded prediction error frame (or semiframe) P or B that must be summed to the information precedingly removed during the motion estimation phase. In case of a P picture, such 35 a resulting sum which may be stored in dedicated memory

buffer is used during the motion estimation process for the successive P pictures and B pictures. These frame memories are distinct from the frame memories that are used for re-arranging the blocks.

5 The MPEG2 decoding will be explained by referring to Figure 3. The first I picture received is decoded by detecting the headers in the bitstream by the following: a HEADER-DETECTION block, a successive inverse VLC decoding, an inverse decoding of the run-
10 level pairs, an inverse quantization, an inverse DCT computation and the successive storing in suitable memory buffers, and used to calculate the prediction error for decoding the successive P and B pictures.

In video broadcasting, the sequences are
15 transmitted or are eventually recorded on a variety of channels and supports, each with its own capacity, speed and cost. Distribution of a film, starting from a master recording, may be made on a DVD (Digital Video Disk) or via satellite or cable. The available
20 transmission band may be different from the one allocated during the coding phase of the video sequence. This raises the problem of re-adapting to the characteristics of new media a bitstream belonging to video pictures originally coded for a channel with a
25 different bit-rate.

More specifically, this implies the need to modify the bit-rate B_1 of a MPEG2 bitstream, expressed in B_1 Mbit/s, and is generated after a coding of the source sequence in a bitstream still coherent to a
30 MPEG2 syntax, with a B_2 bit-rate, where B_2 is different from B_1 . The bit-rate B_1 is a bandwidth measure of the available channel. Such a change of bit-rate may be effected in a very straight forward manner without using dedicated devices.

0025262728292A2B2C2D2E2F2G2H2I2J2K2L2M2N2O2

Since an encoder and a decoder transform respectively a sequence of photographs into a MPEG2 bitstream, and a MPEG2 bitstream into decoded pictures starting from a bitstream coded with an arbitrary B1 5 bit-rate, it is always possible to obtain a bitstream with a B2 bit-rate by simply coupling the output of the decoder to the input of the encoder. This is done after having programmed the latter in order to code with the desired bit-rate B2.

10 This procedure, which may be defined as an explicit transcoding of a bitstream, requires the following steps:

1. inverse Huffman coding;
- 15 2. inverse run-length coding;
3. inverse quantization;
4. inverse Discrete Cosine Transform; and
5. motion compensation.

20 The above steps 1-5 are carried out in the decoder, while the encoder performs the following steps:

1. pre-processing;
- 25 2. motion estimation;
3. calculation of the prediction error;
4. Discrete Cosine Transform;
5. quantization;
6. run-length coding;
- 30 7. Huffman coding;
8. inverse quantization;
9. inverse discrete cosine transform; and
10. motion-compensation.

0097425002-111400

As it may be easily discerned, such a transcoding process entails a very complex computational complexity. The major computational burden of the above noted sequences dwells in the 5 motion estimation step in the direct/inverse cosine transform steps and in the motion compensation step. In contrast, quantization, run-length coding and Huffman coding are relatively less demanding steps.

There is a need for a method of changing the 10 bit-rate of a data stream of video pictures that is relatively easier to implement in hardware form and does not require burdensome calculations.

Summary of the Invention

In view of the foregoing background, it is 15 therefore an object of the present invention to change the bit-rate of a bitstream of video pictures using a reduced number of steps and simplify the required hardware resources for doing so.

This and other objects, features and 20 advantages in accordance with the present invention are provided by a method for producing a bitstream relative to digital video pictures subdivisible into a pair of bitstreams of coded data and control bits, respectively, having a bit-rate different from the bit- 25 rate of an input bitstream.

This result is obtained by dividing the input bitstream into a sequence of data and into a sequence of control bits, and modifying the sequence of control bits obtained as a function of the different bit-rate 30 to be output for producing an output sequence of control bits. The method further includes decoding the sequence of coded data producing an intermediate sequence of decoded data that is successively quantized with a pre-established step and coded for producing an

0924509 - 4 - 100

output sequence of coded data. The output data stream of the desired bit-rate is produced by merging the two output sequences. Optionally, it is possible to dequantize the intermediate sequence of decoded data 5 before carrying out the quantization with the pre-established step.

The method of the invention may be easily adapted to pictures coded according to the MPEG2 standard by making the decoding and coding operations 10 operate in a Huffman decoding followed by a run-length decoding, and in a run-length coding followed by a Huffman coding, respectively. The quantization step is preferably determined by a feed-back/forward rate control technique or by a feed-back/forward rate 15 control technique.

A hardware embodiment of this method may comprise a first circuit block separating the input stream into a sequence of coded data and into a sequence of control bits, and a second circuit block 20 for modifying the sequence of control bits as a function of the different bit-rate that is desired for producing an output sequence of control bits. The hardware embodiment further includes a decoder for the sequence of coded data for producing an intermediate 25 sequence of decoded data, and a quantizer for a pre-established step of the intermediate sequence of data. An encoder is coupled to the output of the quantizer for producing an output sequence of the coded data. A third circuit block merges the two output sequences and 30 outputs a bitstream with the required bit-rate.

Optionally, the device may include a dequantizer for the intermediate sequence of decoded data before the quantizer.

Brief Description of the Drawings

The particular aspects and advantages of the invention will become even more evident through the following description of several embodiments of the 5 invention and by referring to the attached drawings, wherein:

Figure 1 is a block diagram comparing a known coding technique with the method according to the present invention;

10 Figure 2 is a block diagram of an MPEG2 encoder according to the prior art;

Figure 3 is a block diagram of an MPEG2 decoder according to the prior art;

15 Figure 4a is a block diagram of an architecture implementing the method according to the present invention;

Figure 4b illustrates a preferred embodiment of the quantization chain according to the present invention;

20 Figure 5 is a block diagram of an architecture according to the present invention including a control of the feed-back compression rate; and

Figure 6 is a block diagram of an 25 architecture according to the present invention including a control of the feed-forward compression rate.

Detailed Description of the Preferred Embodiments

The bit-rate is determined by the number of 30 bits dedicated to the coding of the quantized DCT coefficients of the prediction error. By operating on the quantization parameter it is possible to increase or decrease the bit-rate. The selection of this

DO NOT EFILE - 6000FTX2600

parameter is made by the control module of the compression rate.

The portions of the bitstream that do not influence the reduction of the bit-rate are simply 5 copied rather than processed. This occurs for the majority of the data relative to the syntax and, above all, for the motion vectors, because the motion field depends solely on the calculations carried out on the source sequence. Since the goal is to obtain a 10 reduction of the bit-rate, the coding process is equivalently represented by the VLC inverse coding and by the run-length decoding. This is in reference to the MPEG2 standard.

It is not necessary to carry out a discrete 15 inverse cosine transform and a motion compensation because the control of the bit-rate occurs in the frequency domain with a net saving of computational processing. Once the quantized DCT coefficients are extracted, they are requantized with a new quantization 20 step. This step is typically different from the quantization step found in the input (source) bitstream, and the run-length and Huffman coding are finally performed.

Optionally, the requantization operation may 25 be preceded by a de-quantization of the DCT coefficients in case it is desired to operate with non quantized values. Substantially, the computational savings derive from eliminating the motion compensation step, the motion estimation step, the direct and 30 inverse discrete cosine transform steps.

A comparison of the method of the invention and a normal coding technique is illustrated in Figure 1. With the method of the invention it is possible to obtain directly an output data stream at the desired 35 bit-rate of B2 Mbit/s through the block

004517752760

MPEG2_TRANSCODER that implements the method of the invention. This block processes an input data stream having a bit-rate of B1 Mbit/s as produced by an MPEG2_ENCODER that codes according to the MPEG2 standard the pixels of a SOURCE_SEQUENCE.

The same result may be obtained

The same result may be obtained by connecting in cascade an **MPEG2_DECODER** and an **MPEG2_ENCODER**.

However, as shown in Figure 1, such an approach implies the generation of a sequence of decoded pictures

10 DECODED_SEQUENCE with the associated costs in terms of processing complexity and time required.

A basic diagram of a hardware embodiment of the method of the invention is shown in Figure 4a. The INPUT_BISTREAM is fed to a circuit block that separates the headers of the sequence and of the GOP (Group Of Pixels), which are successively adapted to the desired bit-rate and sent to a multiplexer that produces the output bitstream.

The PICTURE_HEADER_DETECTION block detects the presence of the control bits of a picture of the video sequence, separating them from the data bits that are sent to a REQUANTIZATION_BLOCK. This block carries out after the Huffman and run-length decoding process a dequantization and a quantization with a pre-established step, which is followed by a run-length coding and a Huffman coding. The step of quantization is determined by the RATE_CONTROL and BUP blocks that store the number of bits produced.

30 A preferred embodiment of the REQUANTIZATION_BLOCK is shown in Figure 4b. The cascade of blocks
perform the above mentioned Huffman decoding (IVLC),
run-length decoding (IRL) and dequantization (IQ),
followed by a quantization (Q) with a step determined
by the QUANTIZATION_PARAMETER, and the run-length (RL) and
35 Huffman (VLC) coding.

The compression rate may be regulated by dedicated multiplexers. There are essentially two multiplexer types: feed-back rate control and feed-back/forward (with pre-analysis) hybrid rate control.

5 The MPEG2, Test Model 5, provides a detailed description of the above mentioned techniques for regulating the compression rate. Other implementations of the above noted control techniques are described in the following European Patent Applications which are
10 incorporated herein by reference in their entirety: 97830591.0, 98830599.1 and 99830560.1. These applications are assigned to the assignee of the present invention.

15 A hardware embodiment of the feed-back technique of rate control is illustrated in Figure 5. The following discussion is provided in reference to this figure. Through the input gate 1 the bitstream is transferred to circuit A. The first analysis takes place in this circuit. If data relative to the syntax
20 of the sequence and of the GOP are detected, they are conveyed through circuit path 2 towards circuit B, which extracts certain format data, and circuit L synchronizes the output thereof.

25 When circuit A detects the start data of the picture, circuit C takes control until a new header of the sequence/GOP/picture is detected. When circuit A starts to transmit picture data, circuit C conveys them through circuit D toward the requantization chain of circuits E-J. In this phase, circuit K provides the
30 quantization parameter, and through circuit 7 collects information on the past performance of the coding process. Circuit L reconstructs the bitstream starting from the contribution of circuit 3 (syntax of the sequence and of the GOP), of circuit 5 (motion vectors)
35 and of circuit 6 (DCT coefficients).

00722500-14000

The alternative technique of rate control may be implemented by the architecture of Figure 6. The following discussion is provided in reference to this figure. Through the input gate 1 the bitstream is 5 conveyed to circuit A. Circuit A carries out a first analysis of the bitstream. If data relative to the syntax of the sequence and of the GOP are detected, they are conveyed through circuit path 2 toward circuit B which extracts certain format data, and circuit P 10 synchronizes the output thereof. When circuit A detects the start data of a picture, circuit C takes control until a new header of the sequence/GOP/picture is detected.

Circuit C controls the timing between the 15 pre-analysis and the recoding. When circuit A starts to transmit picture data, circuit C copies the data in buffer E and simultaneously conveys such data through circuit path 6 towards the requantization chain of circuits G-L. In this phase, circuit O provides the 20 quantization parameter during the preanalysis phase, and circuit M sends the collected data to circuit N which constructs the Bit Usage Profile of the picture.

Thereafter, circuit C switches its output from circuit D towards circuit F so that the original 25 data are read again by circuit E and retransmitted to the requantization chain. Circuit O supplies the quantization parameters of the final coding using the data collected by circuit N during the preanalysis.

Circuit M outputs data towards circuit path 13 and 30 sends the requantized and coded coefficients to circuit P. Circuit C inserts properly the data output by circuit M with the original motion vectors stored in circuit E during the pre-analysis phase. Circuit P reconstructs the bitstream starting from the 35 contributions of circuit 3 (syntax of sequence and

DO NOT DESTROY

GOP), of circuit 8 (motion vectors) and of circuit 13 (DCT coefficients).

To further illustrate the functioning of the device of Figure 6, reference may be made to the 5 following representation in a C pseudo-code of the procedures performed by the main circuit blocks. It is useful to list several functions that are commonly used to access the bitstream: such as ShowBitsS(N) and ShowBitsC(N), which show, without moving from the 10 actual position, the next N bits of the bitstream. The first function reads from input 1, and the second function reads from the picture memory (LOCAL_MEMORY).

Other functions include GetBitsS(N) and GetBitsC(N), which show the next N bits of the input 15 bitstream and of the LOCAL_MEMORY, respectively. The cursor shifts by N positions. The function PutBitsD(bits) and PutBitsC(bits) write the past bits by argument in the output bitstream (14) and in the LOCAL_MEMORY, respectively.

20 The functions MoveBitsSD(N), MoveBitsSC(N) and MoveBitsCD(N) are combinations of GetBits*() and PutBits*() functions which allow the reading and moving of N bits from the input to the output, from the input to the LOCAL_MEMORY and from the LOCAL_MEMORY to the 25 output, respectively.

The function of circuit blocks [A]+[B] include the VideoSequence() procedure that recognizes the header sections of the sequence and of GOP, and outputs them. When the start code of the picture is 30 detected, control is passed to circuit C. In particular:

```
VideoSequence()
{
    while(NextStartCode() != SEQUENCE_END_CODE)
35    {
```

0007425003-144100

```
if (SEQUENCE_START_CODE || GOP_START_CODE)
{
/* copy input data to output */
}

5    else if(PICTURE_START_CODE)
{
/* [C] */
}

10   For circuit block C:
TranscodePictureData()
{
PicturePreanalysis()
PictureReshape()
15 }

In the detail:
PicturePreanalysis()
{
for(i=0; i<= MACROBLOCK_COUNT; i++)
{
MoveBitsSC(MOTION_VECTORS)
mQuant = PreanalysisMQuant() /* rate control [0] */
Requantize(DCTMatrix, mQuant)
BUP[i] = BitCount(DCTMatrix)
25 }

```

The letter procedure carries out the analysis of the picture header, then it begins the macroblock loop until the end of the data section of the picture 30 is reached. The bitstream access functions used in this case are the ReadBits(), PutBitsC() and, above all, MoveBitsSC(). This implies that, while the bitstream is consumed for performing the preanalysis, the read bits are saved in the LOCAL_MEMORY.

The Requantizer() function is self-explanatory, whereas the BitCount() performs the run-length and Huffman coding without writing the result but counting only the bits produced. Such a number is 5 written in the BUP.

At the end of this procedure the situation is as follows. The pointer to the source bitstream is positioned at the end of the data section of the picture. The pointer to the LOCAL_MEMORY is positioned 10 at the start of the LOCAL_MEMORY itself, which contains a copy of the section of data of the picture just read from the source bitstream. In the output file none of the bits relative to the picture has been written yet.

```
Picture Reshape()  
15  {  
    for(i=0; i<= MACROBLOCK_COUNT; i++)  
    {  
        MoveBitsCD(MOTION_VECTORS)  
        mQuant = ReshapeMQuant() /* rate control */  
20        Requantize(DCTMatrix, mQuant)  
        PutBitsD(DCTMatrix)  
    }  
}
```

This routine is very similar to a Picture 25 Preanalysis(), apart from the fact that, the functions to access the data become ReadBits(), PutBitsD() and MoveBitsCD(). At the end of this procedure the situation is as follows. The pointer to the source bitstream is set at the end of the data section of the 30 picture. The pointer to the LOCAL_MEMORY is set at the end of the LOCAL_MEMORY itself, which will be successively emptied to receive the data belonging to the successive picture. The transcoded data of the picture have been written in the output file.

DOIT-6062500-17

For circuit block 0:

```
5     PreanalysisMQuant()
 5     {
 5     /* returns previous picture's mean mQuant */
 5 }
```

The pre-analysis quantization parameter mQuant is the mean of the coding of the last common picture, i.e., of the same type I, P or B.

```
10    ReshapeMQuant()
 10    {
 10    LocalError = BITS_PRODUCED-BUP
 10    IntegralError += LocalError
 10    mQuant = PREANALYSIS_MQUANT + LocalError*PropCoeff
 15      + IntegralError*IntCoeff
 15 }
```

At each coding step, the RATE_CONTROL circuit measures the offset from the ideal profile (LocalError) and calculates also the integral error. The mQuant value is then obtained by applying to the PI controller the coefficients PropCoeff and IntCoeff.
